## Abstract

---

We have modified the conventional cell-linked list method to reduce the number of unnecessary internuclear distance calculations in molecular simulations of systems containing many particles. In the conventional method, the simulation space is partitioned into cells with edge lengths no less than the cutoff distance of the interaction potential ( $r_{cut}$ ). The atoms are assigned to cells according to their spatial positions, and all internuclear distances for atoms within a cell and atoms in the same and nearest neighbor cells are evaluated. While this method ensures that the internuclear separation between all atom pairs within  $r_{cut}$  is calculated, it allows for unnecessary internuclear distance calculations between pairs that are within the volume encompassing the neighbor cells but that are separated by more than  $r_{cut}$ . The modified method presented here allows for reductions in the cell sizes and the number of atoms within the volume encompassing the neighbor cells. These reductions decrease the number of atoms that are outside of the interaction range and the number of unnecessary internuclear distance calculations while ensuring that all internuclear distances within the cutoff range are evaluated. We present algorithms to determine the volume with the minimum number of neighbor cells as a function of cell size and the identities of the neighboring cells. We also evaluate the serial performance using the modified form as functions of cell size and particle density for comparison with the performance using the conventional cell-linked list method.

# 1. Introduction

Popular molecular simulation techniques such as molecular dynamics or Monte Carlo are used to study the physical and chemical processes occurring in systems containing large numbers of atoms at the atomic level (Thompson 1998). These methods require evaluation of either the total potential energy of a system of  $N$  atoms ( $V_{\text{Tot}}$ ) or the gradients of the potential energy. The total potential energy consists of terms that describe the various interactions among the atoms in the system. These terms are usually functions of internal coordinates, such as internuclear distances between two atoms, bond angles among three atoms, or torsional angles among four atoms. For condensed phase modeling, the total potential energy is often described as a sum of two-body interactions over all atom pairs. The interaction terms are typically simple functions of the internuclear distance  $r_{ij}$  between atoms  $i$  and  $j$ :

$$V_{\text{Tot}} = \sum_{i=1}^{N-1} \sum_{j>i}^N V(r_{ij}). \quad (1)$$

The evaluation of equation (1) and the gradients are usually the most computationally demanding steps in a simulation, even if the functional forms for  $V(r_{ij})$  are extremely simple. Brute force evaluation of equation (1) requires the calculation of at least  $N(N-1)/2$  internuclear distances. In a molecular dynamics simulation, each integration step often requires the evaluation of equation (1) and its gradients more than once depending on the integration scheme that is chosen (Allen and Tildesley 1990). It is clear that methods to reduce the computational burdens associated with numerous evaluations of equation (1) are required. The most obvious recent approaches are to modify the codes for scalable platforms. However, modifications of existing algorithms designed to reduce the computational burdens associated with evaluation of equation (1) can be made to increase the serial performance and exploit scalable architectures to achieve enhanced performance. In this work, we present a modification of existing algorithms that were developed to reduce unnecessary computations of the internuclear distances for atom pairs used in the evaluation of equation (1).

Common strategies to reduce the computational demands associated with equation (1) include the use of simple functions to describe the pair interaction potentials and the assumption that the interaction between two particles is negligible beyond a certain cutoff distance,  $r_{\text{cut}}$ . The assumption of a cutoff distance in the interaction potential allows for a reduction in computational time, since the interaction between atoms separated by distances exceeding  $r_{\text{cut}}$  does not need to be calculated. Unfortunately, the easiest and most direct way to determine the set of internuclear distances that are within  $r_{\text{cut}}$  is to evaluate all distances between all pairs and eliminate those that exceed  $r_{\text{cut}}$ . This step requires a potentially large number of unnecessary calculations and might be the most costly computational step in such a simulation.

The order  $N^2$  method described in the preceding paragraph is due to the assumption of pair interaction potentials in equation (1). However, commonly used functions (such as Lennard-Jones or exp-6 forms) are too simple to correctly model all of the anisotropies that exist in many systems. Also, if chemical reactions in the condensed phase are being simulated, more sophisticated potential energy functions are required. Increasingly complex potential energy functions often use many of the internuclear distances evaluated for equation (1) more than once per evaluation of potential energy or force. An example is seen in the potential energy function used in the simulation of detonation (Rice et al. 1996). In this example, the function that describes the interaction for all atoms in the system is

$$V_{\text{tot}} = \sum_{i=1}^N \sum_{j>i}^N \left\{ f_c(r_{ij}) \left[ (2 - \bar{B}_{ij}) V_R(r_{ij}) - \bar{B}_{ij} V_A(r_{ij}) \right] + V_{\text{vdW}} \right\}, \quad (2)$$

where the first set of terms on the right-hand side of equation (2) (within the square brackets) contains the intramolecular interaction terms and includes many-body effects. The  $V_{\text{vdW}}$  term in equation (2) is a modified Lennard-Jones potential that describes the intermolecular interactions. The intra- and intermolecular interaction terms have different interaction ranges and thus sample different sets of internuclear distances out of the total set in the system. The many-body term in the intramolecular interaction portion of equation (2) has the form

$$\bar{B}_{ij} = \frac{1}{2} \left( \left\{ 1 + G \sum_{\substack{k=1 \\ k \neq i, j}}^N f_c(r_{ik}) \exp[m(r_{ij} - r_{ik})] \right\}^{-n} + \left\{ 1 + G \sum_{\substack{k=1 \\ k \neq i, j}}^N f_c(r_{jk}) \exp[m(r_{ij} - r_{jk})] \right\}^{-n} \right). \quad (3)$$

Evaluation of this term for a single i-j atom pair in equation (1) requires knowledge about the remaining (N-2) internuclear distances. If a brute force calculation of the entire set of internuclear distances is performed for each evaluation of the intramolecular interaction between all atom pairs during evaluation of equation (1) using a potential of the form of equation (2), this simulation becomes order  $N^3$ .

A reduction of unnecessary calculations of internuclear distances can be accomplished through the use of the Verlet neighbor list (Verlet 1967). This method requires the construction of a list of neighbors for each atom. An atom's neighbors are usually defined to be all of the atoms that are within a distance slightly greater than the range of the interaction potential. Information about the neighbors is stored in arrays. For the duration of the simulation or until the lists are updated, each atom is assumed to interact only with the atoms on its neighbor list. The internuclear distances, interaction potentials, and forces are evaluated for each atom and its neighbors only. The list may be periodically updated to allow for the movement of atoms into or out of the interaction range. Brute force construction or update of the list requires the evaluation of all  $N(N-1)/2$  internuclear distances. The method has been shown to be efficient when the system contains a relatively small number of atoms (Allen and Tildesley 1990; Morales, Rull, and Toxvaerd 1989). However, as the system becomes larger, the memory requirements for maintaining the neighbor lists become prohibitive. Also, as the mobility of the atoms becomes greater, either the frequency of lists updates must increase or the cutoff distance used in the definition of the neighbors must increase. Either of these requirements increases the computational demands of the Verlet neighbor list method. The example of the detonation simulation is one such case in which the mass flow (moving at supersonic speeds) would require large neighbor cutoff distances and frequent neighbor list updates (Rice et al. 1996).

Alternative methods for the efficient determination of the interacting neighbors for each atom include grid or cell approaches (Allen and Tildesley 1990; Boris 1986; Lambrakos and Boris 1987; Brugè 1993). These approaches partition the simulation space into grids or cells, to which the atoms are assigned by virtue of their positions relative to the cells. Since each cell has an unchanging set of neighboring cells that contain the volume within the distance  $r_{cut}$  of that cell, an atom associated with one of the cells has as its neighbors those atoms assigned to the same or neighboring cells. The implementations of these methods usually assign the atoms to the cells at each integration step. However, the same considerations used for the frequency of updating the Verlet neighbor lists are applicable here. There is some overhead associated with these methods, and they are preferable only for systems that contain more than 1,000 atoms (Allen and Tildesley 1990). These methods substantially reduce the number of unnecessary internuclear distance calculations in evaluating equation (1) but do not completely eliminate unnecessary computations.

In this work, we report modifications to grid-cell methods to further reduce the number of internuclear distance calculations in systems containing larger numbers of atoms. The approach we present is a modification of the conventional method of cell-linked lists as described in detail by Allen and Tildesley (1990). The results show a dramatic decrease in CPU requirements and are amenable to parallelization.

Brugè and coworkers have already provided geometric and systolic parallelization schemes for conventional implementations of Verlet neighbor lists and conventional cell-linked lists (Brugè 1993; Brugè and Fornili 1990a, 1990b). These have shown significant decreases in computation times, and we refer the readers to such information. Our intent here is to modify the algorithms to accelerate both serial and scalable performance. We describe the modifications and demonstrate the performance on serial platforms in this work. Future work will focus on scalability and further modifications to enhance performance. We are confident that some of the scalable methods set forth by Brugè and coworkers (Brugè 1993; Brugè and Fornili 1990a, 1990b) will be applicable to these algorithms.

## 2. Method of Cell-Linked Lists

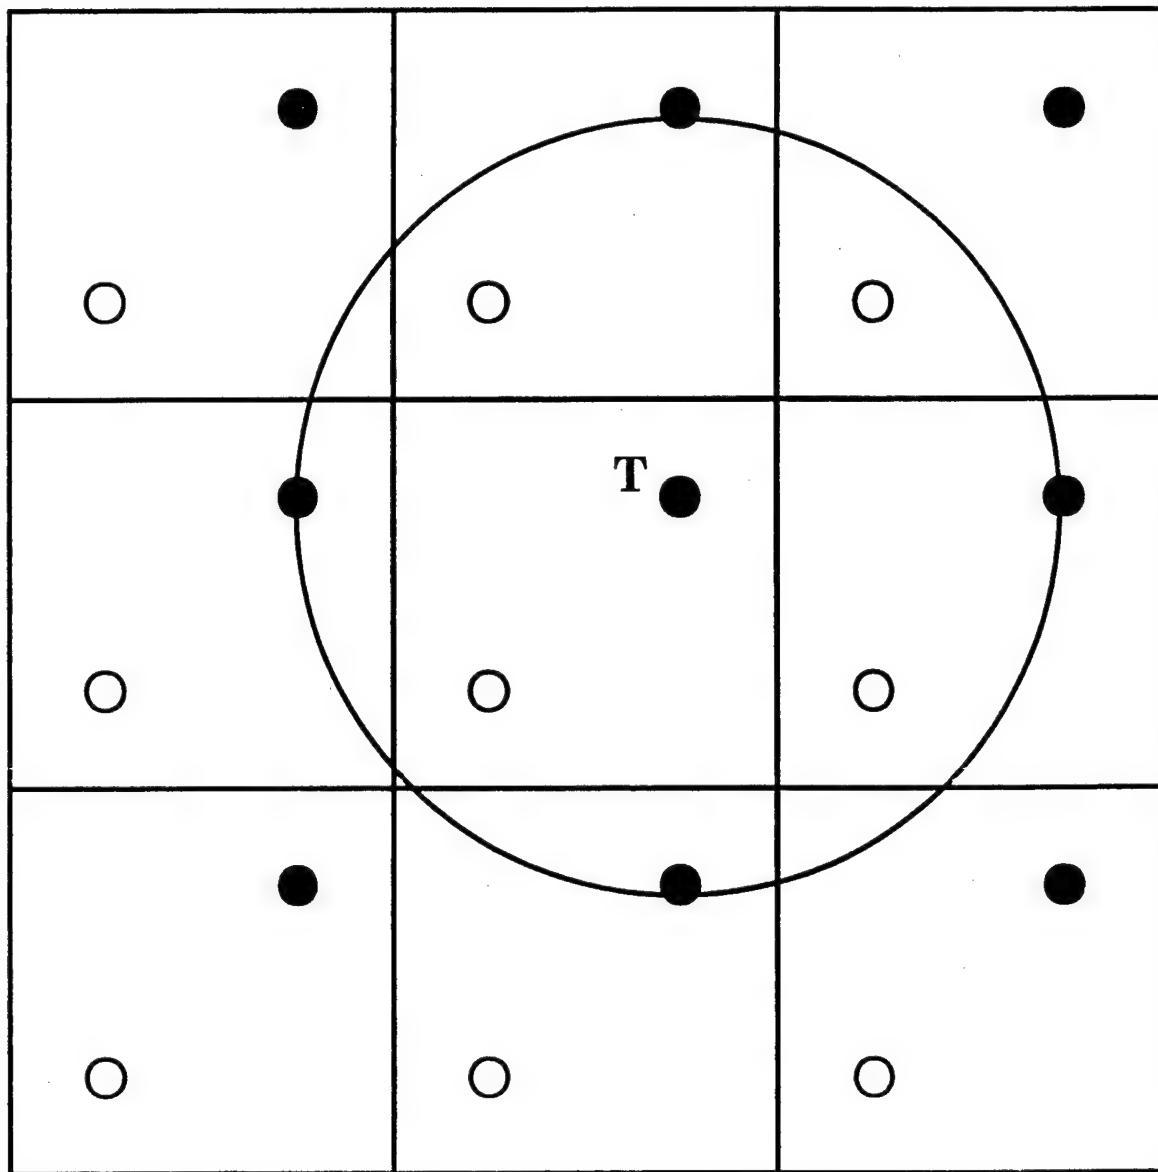

**2.1 Conventional Method.** The conventional method of cell-linked lists is well described by Allen and Tildesley (1990). We, like they, describe our variation of the method in two dimensions, but the method can be generalized to include three dimensions. The modification we present is similar to one suggested by Allen and Tildesley (1990)—that the cell size be reduced so that no more than one atom can occupy a cell.

In the conventional method of cell-linked lists, the simulation space is partitioned into cells, the edges of which being no smaller than the cutoff distance of the interaction potential. The atoms are then assigned to the various cells by virtue of their position in the simulation space. A linked list of the atom indices is created during the sorting procedure. Also, at the beginning of a simulation, an array that contains a list of cell neighbors for each cell is created. The list remains fixed unless the simulation space changes during the simulation (see, for example, Rice et al. [1996]).

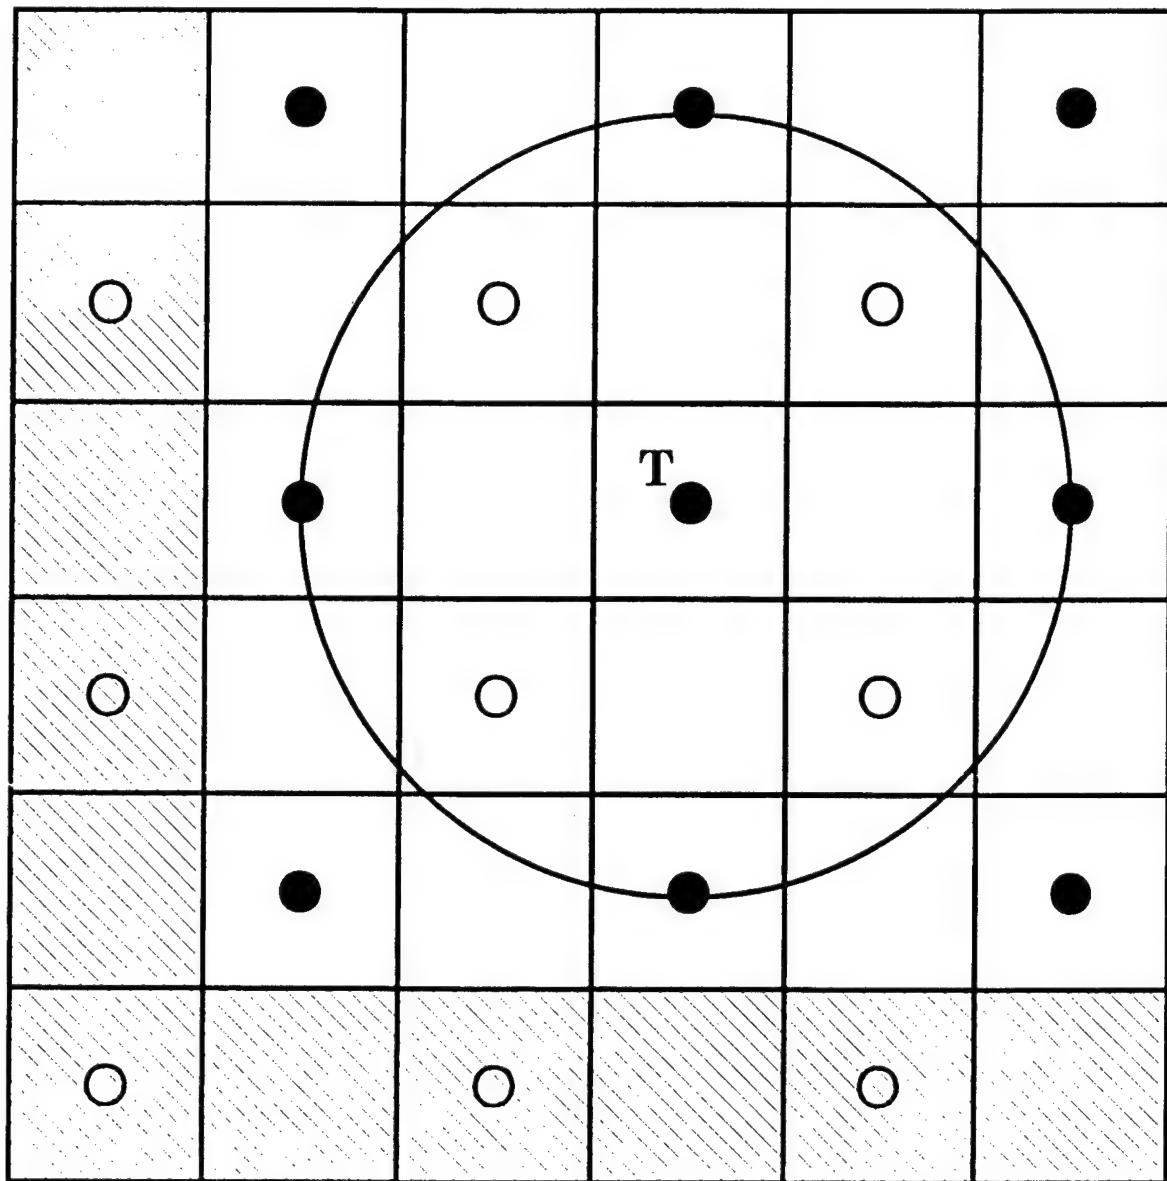

A cell  $i_{cell}$  has as its neighbors any cell that contains at least one point that is within the distance  $r_{cut}$  of any point within  $i_{cell}$ . Since the conventional method requires that the edges of each cell be no smaller than  $r_{cut}$ , each cell has eight nearest neighbors (we are assuming periodic boundary conditions in both dimensions of our two-dimensional example). These requirements ensure that all atoms that are within the interaction range of any atom within  $i_{cell}$  are assigned to the eight nearest-neighbor cells of  $i_{cell}$  or  $i_{cell}$  itself. All atoms occupying cells other than these are outside the interaction range of any atom located within  $i_{cell}$ . Figure 1 illustrates the division of a region of the simulation space into cells. In this figure, both the x and y cell edges (denoted as  $l_x$  and  $l_y$  hereafter) equal  $r_{cut}$ . Evaluation of equation (1) occurs through looping over the cells using the linked list of atoms rather than accessing the atom indices sequentially as written in equation (1).

This method dramatically reduces the number of unnecessary internuclear distance calculations that would result from a brute force calculation of all  $N(N-1)/2$  internuclear distances. However, modifications can be made to further reduce the number of unnecessary distance calculations. In the conventional method, the distances between all atom pairs located within the rectangular area of  $9l_x l_y$  are calculated. Assuming the limiting case  $l_x = l_y = r_{cut}$ , the area within which all distances are calculated is  $9r_{cut}^2$ . The area within the cutoff radius for a single atom is only  $\pi * r_{cut}^2$ . Thus, the traditional cell-linked list method calculates distances between all atom pairs within an area that is almost three times larger (or more, since  $l_i \geq r_{cut}$ , where  $i = x$  or  $y$ ) than that actually required for an atom. This dramatic difference is illustrated by comparing the area within the shaded circle centered on the atom labeled "T" with the area for the cell containing T and its neighboring cells in Figure 1. The shaded circular area illustrates the range of interaction for atom T. Implementation of the conventional cell-linked list for this example would result in nine unnecessary internuclear distance calculations.

**2.2 Modified Method of Cell-Linked Lists.** The main modification of the method is in the definition of the sizes of the cells. By dividing the simulation space into smaller rectangular cells, each atom is surrounded by a group of cells that better approximates the area of interaction for that atom. For example, in Figure 2, we have divided the original rectangular cells from Figure 1 into fourths. The length of each cell is now  $1/2r_{cut}$ . The neighboring cells to that containing the labeled atom T are the surrounding first and second shells of cells. The area for this set of neighboring cells is  $6.25r_{cut}^2$ , which is approximately one-third smaller than the rectangular area that would be considered in the conventional approach (see Figure 1). Also, the number of unnecessary internuclear distance calculations has been reduced to four. However, the number of neighboring cells to that containing atom T has increased from 8 to 24. Thus, the area has been substantially reduced, but the number of neighboring cells has increased by a factor of 3. There is an increase in memory requirements associated with the linked lists upon increasing the number of neighboring cells.

**Figure 1. Illustration of the Conventional Cell Method in Two Dimensions; Simulation Box Is Partitioned Into  $3 \times 3$  Square Cells; Edge Length of Each Cell Is  $r_{cut}$ . The Shaded Circle Centered on Atom T Has Radius  $r_{cut}$  and Denotes the Range of Interaction for Atom T. In This Method, the Eight Outer Cells Are Considered Neighbors of the Central Cell That Contains Atom T.**

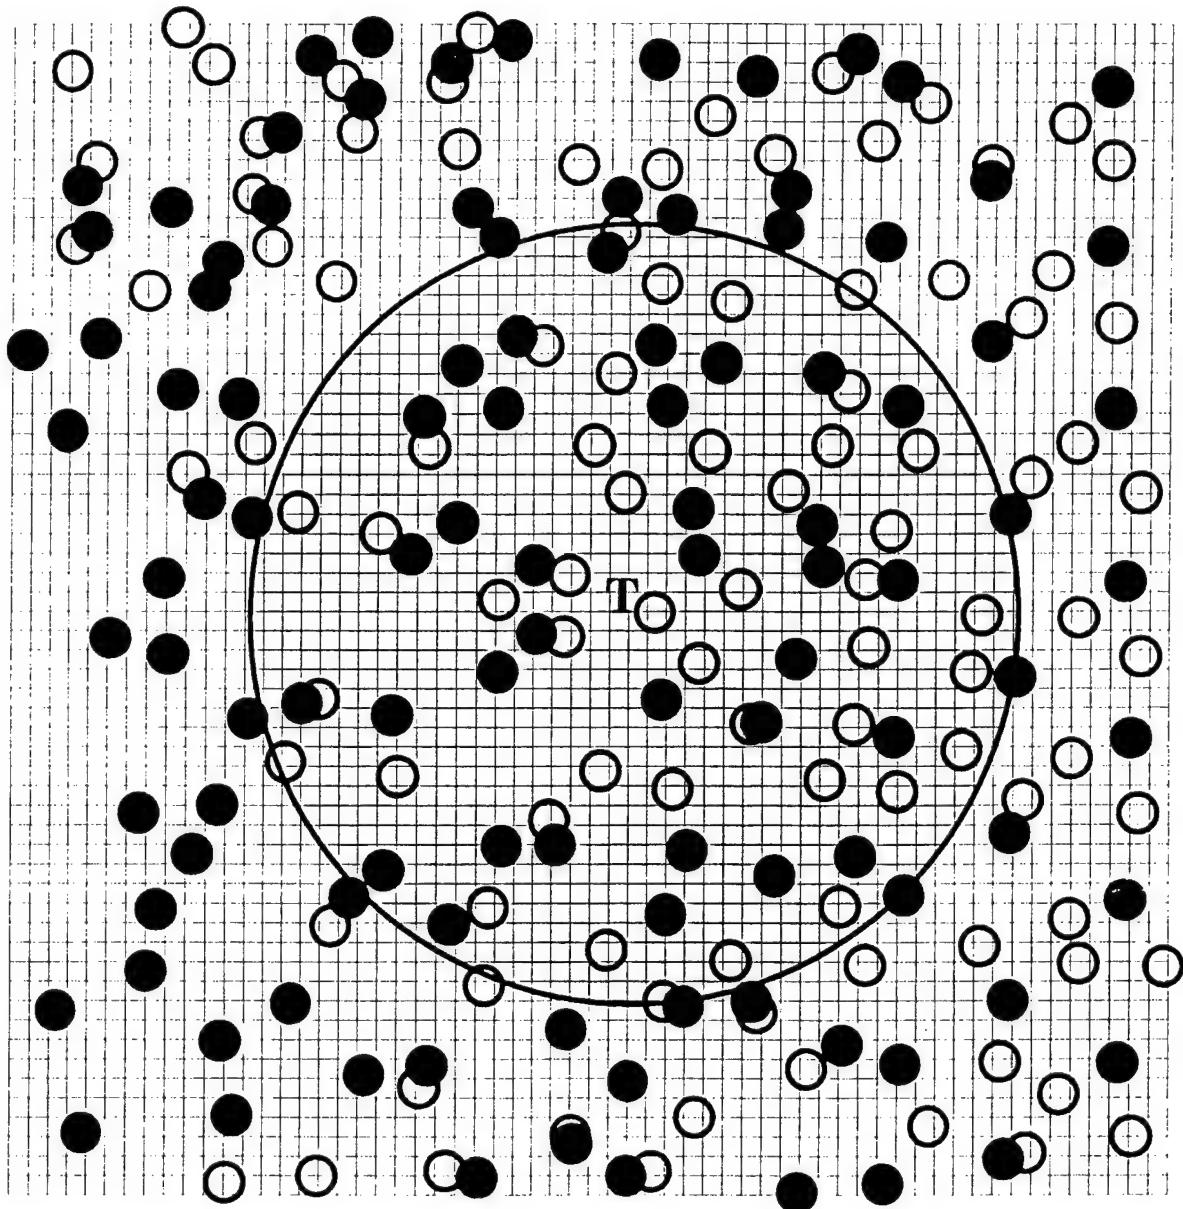

**Figure 2. Illustration of the Conventional Cell Method in Two Dimensions; Simulation Box Is Partitioned Into  $6 \times 6$  Square Cells; Edge Length of Each Cell Is  $r_{cut}$ . The Hatched Area Denotes the Cells That Are Not Considered to Be Neighbors of the Cell Containing Atom T in the Modified Cell-Linked List Method.**

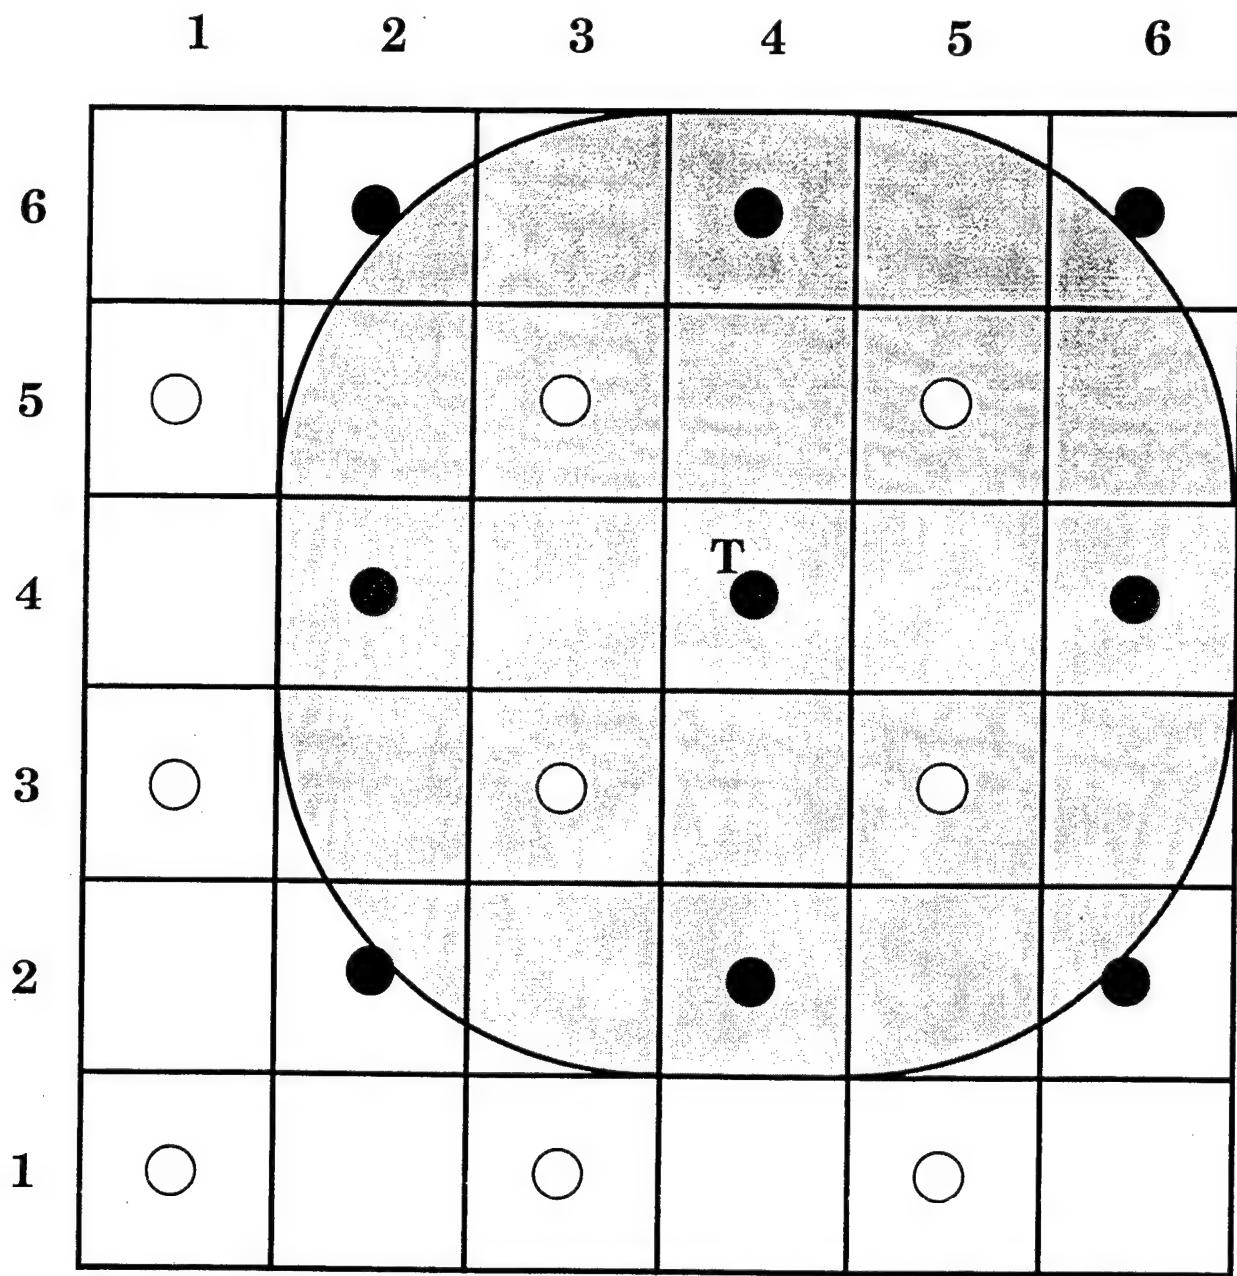

In the simple examples shown in Figures 1 and 2, the division of the original cell size into fourths has reduced the number of unnecessary internuclear distance calculations from nine to four, and a further reduction in cell size would probably not result in additional savings. A system whose atoms are arranged such that the density is not uniform might benefit from further reduction of the cell sizes to the point that the sphere of interaction of an atom is closely approximated by a set of small rectangular cells. Such an example is given in Figure 3, which has overlaid the positions of atoms behind a detonation wave (Rice et al. 1996) (a high dense region) onto a grid of cells with edge lengths  $l_x = l_y = 1/20r_{cut}$ . It is clear that use of cells with the sizes shown in Figures 1 or 2 would require many unnecessary internuclear distance calculations for the atomic arrangement in Figure 3.

Note that many of the neighboring cells to that containing the labeled atom T in Figure 3 are empty. There is overhead associated with determining whether a cell is occupied. Also, more memory is required to maintain the cell-linked list and the neighbor list, since as the cell sizes decrease the number of cells and the number of neighboring cells for each cell increase. While this method reduces the unnecessary distance calculations, there is a point at which the reduction in the size of the cell requires more computation in overhead than it saves in eliminating unnecessary distance calculations. The optimum cell size might vary from machine to machine and implementation to implementation. Therefore, it is desirable to use an algorithm that allows for the cell size to be changed easily to accommodate portability.

**2.3 Offset Mapping Method.** As cell sizes decrease, memory requirements for storage of neighbor information increase and are potentially a limitation on the use of the modified cell-linked list scheme. This problem can be reduced by the determination of neighboring cells through a list of relative cell index offsets, similar in spirit to that presented in the Monotonic Logical Grid (MLG) approach (Boris 1986; Lambrakos and Boris 1987). After partitioning the simulation space into cells, each cell is assigned a grid cell index (i,j,k) that corresponds to its location in a Cartesian reference frame (x,y,z). Figure 4 illustrates the two-dimensional grid overlaid on the simulation box shown in Figure 2. In this example, the grid indices are assigned

**Figure 3. Simulation Box Partitioned Into  $60 \times 60$  Square Cells; Edge Length of Each Cell Is  $1/20r_{cut}$ . The Atoms That Are Illustrated on This Grid Were Taken From Results of a Molecular Dynamics Simulation of Detonation and Correspond to the High Dense Region Behind the Detonation Front (Rice et al. 1996).**

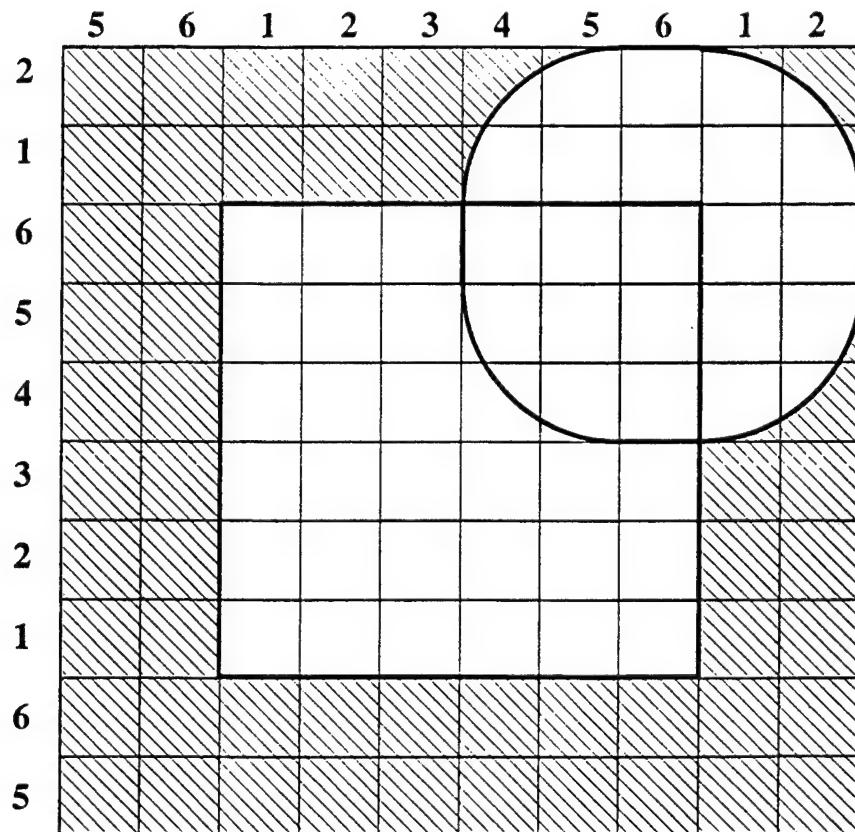

**Figure 4.** Illustration of the Conventional Cell Method in Two Dimensions; Simulation Box Is Partitioned Into  $6 \times 6$  Square Cells; Edge Length of Each Cell Is  $1/2r_{cut}$ ; “Shaped” Neighbor Region (Shaded Area) Illustrated.

relative to cell (1,1), located at the lowermost cell on the left-hand side of the figure. The cell that contains the labeled atom T is located at the fourth column (x direction) and the fourth row (y direction). Thus, the grid index for this cell is (4,4). The set of cells that are within the interaction range ( $r_{cut}$ ) for all points in cell (4,4) consists of the first and second nearest neighbors, each of which has a set of grid indices that can be described as relative offsets to (4,4). Each cell in the simulation box has the same set of relative grid index offsets as (4,4). This set can be stored in a relative offset array, which is illustrated for this example in the upper portion of Figure 5.

Determination of the relative cell index offsets of the neighbors is straightforward, particularly if the area encompassing the neighbors is rectangular. In this example, the rectangular area containing all neighboring cells has dimensions of  $2r_{cut} + l_i$ , where  $i = x$  or  $y$ . However, the shape of the area containing the neighboring cells is not limited to a rectangle. Further reductions in unnecessary distance calculations can result if the area containing the neighboring cells resembles a circle. Since the set of neighbors must contain all of the area within the interaction range of any point within the cell, we want the minimum set of cells that make up this “neighbor region.” Rounding the corners of the rectangular neighbor region will shape the neighbor region to approximate a circle. Again, using our simple example, we illustrate this in the shaded portion of Figure 4. The rounded corners represent the portions of circles with radius  $r_{cut}$  that are centered on the corners of the cell that contains T. In this example, the number of cells containing the neighbor region is the same as that of the rectangular area. However, as the cell sizes are reduced, the number of cells containing the neighbor region will be less than those of the corresponding rectangular area, and the set of cells contained in the neighbor range will more closely approximate a circle.

To determine the minimum number of cells contained in the neighbor region, we first assume a rectangular simulation box that is larger than twice the cutoff radius in all dimensions. The box is then partitioned into cells of a desired size. At this point, assume that the central cell in this box has the grid index (0,0). Only the neighbor cells contained in one quadrant of this simulation

This Is the Geometric Representation of the Mapping Array. The Numbers Along the Left-Hand Side and Top of the Figure Indicate the Packing of the Mapping Array.**

box need to be identified, since the remaining neighboring cells that occupy the other quadrants can be generated from symmetry. We consider the top right-hand quadrant in our illustration.

The process of identifying the neighbor cells in this quadrant begins with the calculation of the range of the cells along the  $x$  axis. The grid index for the furthermost neighbor cell in the  $x$  direction,  $xlen$ , is defined as  $xlen = \text{floor} (r_{\text{cut}} / l_x + 1)$ . Each cell  $(ix,0)$  that is between cells  $(0,0)$  and  $(xlen,0)$  is a neighbor of  $(0,0)$ . [Due to the symmetry of the system, all cells  $(jx,0)$  that include or are between  $(0,0)$  and  $(-xlen,0)$  are also neighbor cells.] We then determine the range in the  $y$  direction as follows. For each cell  $(ix,0)$  including or between  $(0,0)$  to  $(xlen,0)$ , the grid index for the furthermost neighbor cell in the  $y$  direction from cell  $(ix,0)$  is defined as  $ylen(ix) = \text{floor} [\sqrt{r_{\text{cut}}^2 - [(ix-1) * l_x]^2} / l_y + 1]$ . All cells that include or are between  $(ix,0)$  to  $[ix, ylen(ix)]$  are added to the list of neighbor cells. The process ensures that any cell whose lower left-hand corner is less than  $r_{\text{cut}}$  from the upper right corner of the cell  $(0,0)$  is a neighbor. A sample FORTRAN code for this process is given in the Appendix.

In a simulation, when a cell with grid index  $(i,j)$  is selected, the neighboring cells are identified by simply adding the relative cell index offsets that are determined at the beginning of the simulation to the cell grid index (see Figure 5 for the simple example presented in this work). If only half of the neighbors are required in the calculations, only the offsets in the first and second quadrants should be used, except those from  $(-xlen,0)$  to  $(-1,0)$ . In our example here, in which we have found the neighbors in the upper right-most quadrant, we may just add the offsets from  $(-ix,1)$  to  $[-ix, ylen(ix)]$  with  $ix = -1$  to  $xlen$ .

This method as described up to this point is sufficient for determining neighbors for cells that are far enough from the edges of the simulation box such that none of the neighbors should be minimum images. However, for cells on or near the edge of the simulation box, the method fails. Again, we use our simple example described in Figure 2. In Figure 5, we have reproduced the simulation box of Figure 2 and surrounded it with a shell of “ghost” cells (hatched area) that is two cells deep in both dimensions. Overlaying the offset list (upper portion of Figure 5) on cell  $(6,6)$ , which is the geometric equivalent of simply adding the offset list indices to  $(6,6)$ , would

result in identifying as neighboring cells those with grid indices ranging from (4,4) to (8,8). This is clearly wrong because the cells with indices greater than 6 are not defined. To remedy this, a mapping array has been developed to correctly map the two-dimensional relative grid cell index offsets to the appropriate set of neighbor cells while properly taking into account the boundary conditions of the simulation. The mapping array for the simple example given in this report (assuming periodic boundary conditions in both directions) is shown in the bottom portion of Figure 5. It is constructed using the column and row designators that border the top and left-hand side of the two-dimensional array in the bottom portion of Figure 5. We illustrate its use as follows. In this simple example, one of the neighbor cells has relative cell index offset (0,2). Adding the relative cell index offset (0,2) to cell (6,6) addresses mapping array element (6,8). According to the mapping scheme, the element (6,8) of the mapping array contains the grid cell index (6,2). Cell (6,2), which corresponds to relative cell index offset (0,2), is the appropriate neighbor for cell (6,6) according to the periodic boundary conditions established for this example. As for the neighbor list, this map array increases in size with decreasing cell size.

By combining the neighbor offset list with the mapping array, the computation of and memory used for storing the neighbor information are kept at reasonable levels, even for very small cell sizes. There are four major arrays associated with this method. These are the list, the overlay, the listhead (which contains the index of the particle that is used to address the element of the linked-list array) (Allen and Tildesley 1990), and the map arrays. The size of the list array always equals the number of atoms. The size of the overlay array is proportional to the interaction range divided by the volume of the cell. The size of the listhead array equals the number of cells, and the size of the mapping array equals the total number of cells and ghost cells. When the number of cells is larger than the number of atoms, then the listhead and mapping arrays require the most memory. However, this method becomes inefficient before the number of cells equals the number of atoms. Therefore, in any reasonable use of this method, the list array has the largest memory requirement.

**2.4 Distance Lists.** As noted earlier, often more complex functions reuse information in the evaluation of equation (1), such as those systems that use potentials described in

equations (2) and (3). This form of interaction potential requires that the internuclear distances be used many times in a single evaluation of the potential energy or forces. Recalculations within a single integration step significantly increase the computer time required for a molecular dynamics simulation. To overcome this problem, we implemented lists that contain information about atom pairs for reuse in the evaluation of the interaction potential and forces. This would be unnecessary for models that assume pair-additive interaction potentials such as the Lennard-Jones or exp-6 potentials, since the internuclear distances for each pair are used only one time per evaluation of forces. But for functions such as those presented in equations (2) and (3), there are several terms that could benefit from storage of the internuclear distances. These include the  $\exp(-g_{ik})$  terms, the  $f(r_{ik})$  terms, corresponding derivatives  $x_{ik}$  and  $y_{ik}$ , distance  $r_{ik}$ , and the atom index of the neighbor. This information can be generated before or during every call to the potential energy and force subroutine using the linked-list method and neighbor list. If the distance is within the intramolecular interaction range, all information that can be reused is calculated and stored. Given an atom pair  $ij$ , the stored information corresponding to that pair can easily be accessed during the evaluation of the potential energy and forces for that pair. Since the number of atom pairs can be large compared to the number of atoms, blocking techniques can be used for the storage of the atom pair information to minimize the memory required to store the atom pair information. In a blocking method, the atom pair information is calculated and stored for only a small number of cells in the simulation space at a time. The potential for these cells is calculated, and as the atom pair information is no longer needed, it is replaced by atom pair information for other nearby cells that are used next.

### 3. Results

Although the description of the procedure given in the preceding section is given in two-dimensional terms, the method is tested herein in a three-dimensional application. Six cubic simulation boxes that differ in size have been chosen to evaluate this methodology. The six simulation boxes consist of 27 ( $3 \times 3 \times 3$ ), 64 ( $4 \times 4 \times 4$ ), 125 ( $5 \times 5 \times 5$ ), 216 ( $6 \times 6 \times 6$ ), 343 ( $7 \times 7 \times 7$ ), and 512 ( $8 \times 8 \times 8$ ) cubic cells. Each cell has edge lengths just greater than  $r_{cut}$ . The different

simulation boxes are denoted hereafter as simulation box 3, 4, 5, 6, 7, and 8, respectively. All calculations were performed serially on an SGI Onyx with four 195-MHz R10000 processors with 1.5 GB of main memory and 4 MB of secondary cache per processor.

The CPU time used to evaluate the internuclear distances using this method as a function of system size and particle density is given in Table 1. For the evaluation using the cell-linked list methods, we report only the times for actual evaluation and do not include any initialization. The initialization, which includes setting up the mapping array and the relative cell offset list, is relatively fast and is only done once. The times reported are the averages for 20 separate evaluations of neighbors, and the timings include the construction of the linked lists for each evaluation. To check the method, all atom pairs were calculated and compared to those calculated through from the brute force method. In Table 1, the variable  $N_{div}$  denotes the number of divisions along an edge of the simulation box. For example, for simulation box 3,  $N_{div} = 3$  partitions each of the three edges of the box into three sections. The simulation box has a total of 27 cells. This value of  $N_{div}$  corresponds to the conventional cell-linked list method.  $N_{div} = 0$  indicates that the cell-linked list method has not been used, and all  $N(N-1)/2$  internuclear distances are calculated. The calculations for  $N_{div} = 0$  are denoted as "brute force" calculations.

It has been established that the conventional cell-linked list method is superior to the brute force approach for systems in which the dimensions are large compared to the cutoff radius of the potential (Brugè 1993). We have seen the same result in this study. Table 1 gives the times for evaluation of the internuclear distances as a function of particle density and  $N_{div}$  for the six simulation boxes and the different methods. For simulation box 3, the execution times of the conventional and modified cell-linked list methods for low densities are greater than that of the brute force method. At higher densities, there is a slight speed-up using the modified cell-linked list method over the brute force approach. Note that for all densities for simulation box 3, the conventional method is slower than the brute force method. For systems that are larger than simulation box 3, however, the performance of the conventional and modified cell-linked list methods given here are superior to that of the brute force method. For the largest simulation box (box 8), there is a 90–97% reduction in CPU time over the brute force method.

**Table 1. Time (in Milliseconds) Required to Evaluate Internuclear Distances for Systems of Different Sizes and Particle Densities**

<sup>a</sup> Percent reduction of execution time relative to that using the conventional cell-linked list method.

<sup>b</sup> Bnfe Force method (see text).

<sup>c</sup> Conventional cell-linked list method (see text).

Further comparison of the modified method is made to the conventional cell-linked results rather than those using the brute force method. Table 1 provides a percent reduction in time using the modified cell-linked list method over the conventional method, and Figure 6 provides an illustration. Each curve in each frame of Figure 6 shows that the percent time reduction first increases with increasing  $N_{div}$ , then decreases as  $N_{div}$  becomes larger. The subsequent decrease in performance with increasing values of  $N_{div}$  becomes more pronounced for systems with low particle densities. For example, the curves for densities of 27 and 64 particles per cell show that the modified cell-linked list method is much slower than the conventional method at large values of  $N_{div}$ . Conversely, the percent time reduction at large values of  $N_{div}$  for high densities ( $>343$  particles per cell) is only slightly less than the maximum value, indicating further time reduction does not necessarily occur with increased partitioning of the simulation space (reduction in cell size). This effect suggests that although the number of unnecessary internuclear distance calculations is decreasing with increasing  $N_{div}$  (see Table 2), the computational costs for the overhead associated with using a smaller cells are increasing and will eventually outweigh the savings realized from the reduced number of internuclear distance calculations.

## 4. Conclusions

It is clear that as advances in scalable architectures continue, more sophisticated molecular simulations requiring more atoms and more complex interaction potentials will be attempted. It is because of this expectation that we have modified the traditional cell-linked list method to reduce unnecessary internuclear distance calculations for larger and more complex systems. We have shown a significant increase in speed of the evaluation of information needed for a molecular simulation through the reduction of unnecessary internuclear distance calculations. Although we have developed this algorithm for acceleration on serial machines, future efforts will invoke strategies for further increased performance on scalable architectures.

<sup>a</sup> The number of internuclear distances that are within the cutoff distance and are required to be calculated in an evaluation of equation (1) and its derivatives.

<sup>b</sup> Corresponds to the brute force evaluation of the  $N*(N-1)/2$  internuclear distances in a system of  $N$  particles.

<sup>c</sup> Corresponds to the conventional method of cell-linked lists.

**INTENTIONALLY LEFT BLANK.**

**Appendix:**  
**Sample FORTRAN Code**

**INTENTIONALLY LEFT BLANK.**

```

! Cutoffr is the cut off radius. Maxdim is the maximum coordinates for the simulations,
! mindim is the minimum. Ndiv is the number of divisions that the simulation is divided into.
! All of these are arrays of length 2.
cr2 = cutoffr * cutoffr
clen = (maxdim - mindim) / ndiv
len = int(cutoffr / clen) + 1
maxlen = len(2)

! Iterate from the cell immediately next to the test cell to the last cell in the x direction.
! Since the height above the test cell is always the same as the height above the cell
immediately
! next to it we don't calculate it here. We start at 2 just for array index reasons.
do i = 2,len(2) + 1

    ! Calculate the height above the current cell.
    lengths(i) = floor(sqrt(cr2 - ((i - 2) * clen(2))**2)/clen(1) + 1)

enddo

! Taking advantage of the above mentioned symmetry
lengths(1) = lengths(2)
n = 0

! Time to replicate the cells for all quadrants and create the offset list.
! Loop over every cell along the x dimension.
do i = -len(2),len(2)

    ai = abs(i) + 1

    ! Loop over every cell along the y axis for column i
    do j = -lengths(ai),lengths(ai)

        ! Don't include cell (0,0)
        if(i .ne. 0 .or. j .ne. 0) then

            n = n + 1
            overlay(n,1) = i
            overlay(n,2) = j

        endif
    enddo
enddo

```

| <p>We have modified the conventional cell-linked list method to reduce the number of unnecessary internuclear distance calculations in molecular simulations of systems containing many particles. In the conventional method, the simulation space is partitioned into cells with edge lengths no less than the cutoff distance of the interaction potential (<math>r_{cut}</math>). The atoms are assigned to cells according to their spatial positions, and all internuclear distances for atoms within a cell and atoms in the same and nearest neighbor cells are evaluated. While this method ensures that the internuclear separation between all atom pairs within <math>r_{cut}</math> is calculated, it allows for unnecessary internuclear distance calculations between pairs that are within the volume encompassing the neighbor cells but that are separated by more than <math>r_{cut}</math>. The modified method presented here allows for reductions in the cell sizes and the number of atoms within the volume encompassing the neighbor cells. These reductions decrease the number of atoms that are outside of the interaction range and the number of unnecessary internuclear distance calculations while ensuring that all internuclear distances within the cutoff range are evaluated. We present algorithms to determine the volume with the minimum number of neighbor cells as a function of cell size and the identities of the neighboring cells. We also evaluate the serial performance using the modified form as functions of cell size and particle density for comparison with the performance using the conventional cell-linked list method.</p> |                |  |                                    |

## USER EVALUATION SHEET/CHANGE OF ADDRESS

This Laboratory undertakes a continuing effort to improve the quality of the reports it publishes. Your comments/answers to the items/questions below will aid us in our efforts.

1. ARL Report Number/Author ARL-TR-1956 (Mattson [Rice]) Date of Report June 1999

2. Date Report Received \_\_\_\_\_

3. Does this report satisfy a need? (Comment on purpose, related project, or other area of interest for which the report will be used.) \_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_

4. Specifically, how is the report being used? (Information source, design data, procedure, source of ideas, etc.) \_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_

5. Has the information in this report led to any quantitative savings as far as man-hours or dollars saved, operating costs avoided, or efficiencies achieved, etc? If so, please elaborate. \_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_

6. General Comments. What do you think should be changed to improve future reports? (Indicate changes to organization, technical content, format, etc.) \_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_

Organization \_\_\_\_\_

CURRENT  
ADDRESS

Name \_\_\_\_\_ E-mail Name \_\_\_\_\_

Street or P.O. Box No. \_\_\_\_\_
